Are neutrino oscillations a non stationary phenomenon?

S. Bilenky
JINR(Dubna)TUM (Munchen)

March 10, 2009
Discovery of neutrino oscillations is one the most important recent discoveries in particle physics. It is a common opinion that small neutrino masses and peculiar neutrino mixing is a signature of a new beyond the Standard Model Physics. In the next generation of neutrino oscillation experiments (Super beam, $\beta$-beam, Neutrino Factory) a very high accuracy in the measurement of neutrino oscillation parameters is planned. Are we sure that the theory of neutrino oscillations is fully justified? Are there open problems in the theory?
Investigation of neutrino oscillations is based on the following assumptions

1. Neutrino interaction is the Standard Model CC and NC interaction. The standard leptonic CC is given by

\[ j^\text{CC}_\alpha(x) = 2 \sum_{l=e,\mu,\tau} \bar{\nu}_{lL}(x) \gamma_\alpha l_L(x) \]

2. Neutrino mixing

\[ \nu_{iL}(x) = \sum_{i=1}^{3} U_{li} \nu_iL(x) \]

\( U \) is an unitary PMNS mixing matrix and \( \nu_i(x) \) is the field of neutrino (Majorana or Dirac) with mass \( m_k \).

This last relation is the relation between fields. What are observable consequences for neutrino oscillations?
All existing neutrino oscillation data can be described if we assume that

- The number of massive neutrinos is equal to the number of the flavor neutrinos (three)
- The neutrino transition probability is given by the expression

\[ P(\nu_l \rightarrow \nu_{l'}) = \left| \sum_{i=1}^{3} U_{l'i} e^{-i\Delta m_{ki}^2 \frac{L}{2E}} U_{li}^* \right|^2 \]

\[ \Delta m_{ki}^2 = m_i^2 - m_k^2, \text{ } k \text{ is fixed} \]

\[ P(\nu_l \rightarrow \nu_{l'}) \text{ depends on } \Delta m_{12}^2, \Delta m_{23}^2, \theta_{12}, \theta_{23}, \theta_{13}, \delta \]
Two neutrino oscillation parameters are small

\[ \frac{\Delta m_{12}^2}{\Delta m_{23}^2} \simeq 3 \cdot 10^{-2}, \quad \sin^2 \theta_{13} \lesssim 5 \cdot 10^{-2} \]

In the leading approximation

\[ \Delta m_{23}^2 \frac{L}{2E} \gtrsim 1 \text{ (atmospheric and LBL experiments)} \]

\[ P(\nu_\mu \rightarrow \nu_\mu) = 1 - \frac{1}{2} \sin^2 2\theta_{23} (1 - \cos \Delta m_{23}^2 \frac{L}{2E}) \]

\[ (\nu_\mu \leftrightarrow \nu_\tau) \]

\[ \Delta m_{12}^2 \frac{L}{2E} \gtrsim 1 \text{ (KamLAND experiment)} \]

\[ P(\bar{\nu}_e \rightarrow \bar{\nu}_e) = 1 - \frac{1}{2} \sin^2 2\theta_{12} (1 - \cos \Delta m_{12}^2 \frac{L}{2E}) \]

\[ (\bar{\nu}_e \leftrightarrow \bar{\nu}_{\mu,\tau}) \]

Solar neutrino data are described by two-neutrino $\nu_e$ survival probability in matter which depends on $\Delta m_{12}^2$ and $\sin^2 \theta_{12}$

In the leading approximation decoupled two-neutrino oscillations in two regions of $\frac{L}{E}$
From the analysis of the data of the atmospheric S-K experiment the following 90% CL ranges were obtained

\[ 1.9 \cdot 10^{-3} \leq \Delta m^2_{23} \leq 3.1 \cdot 10^{-3} \text{eV}^2, \quad \sin^2 2\theta_{23} > 0.9. \]

The results of the S-K experiment have been confirmed by the accelerator K2K and MINOS LBL neutrino oscillations experiments. From the analysis of the MINOS data

\[ \Delta m^2_{23} = (2.38^{+0.20}_{-0.16}) \cdot 10^{-3} \text{eV}^2, \quad \sin^2 2\theta_{23} > 0.84 \ (90\% \ CL) \]

From the global analysis of the data of reactor KamLAND experiment and the data of the solar neutrino experiments it was found

\[ \Delta m^2_{12} = (7.59^{+0.21}_{-0.21}) \cdot 10^{-5} \text{eV}^2, \quad \tan^2 \theta_{12} = 0.47^{+0.06}_{-0.05} \]
Neutrino production, propagation and detection in the case of the neutrino mixing

Let us consider a CC decay

\[ a \rightarrow b + l^{(+)} + \nu \]

The state of the final particles

\[ |f\rangle = \sum_i |\nu_i\rangle |l^+\rangle |b\rangle \langle \nu_i l^+ b | S |a\rangle \]

\(|\nu_i\rangle\) is the state of the left-handed neutrino with mass \(m_i\) and momentum \(p_i\).

In matrix element \(\langle \nu_i l^+ b | S |a\rangle\) at neutrino energies \(E \gtrsim \text{MeV}\), mass-squared differences can be neglected

\[ \frac{\Delta m^2_{12}}{E^2} \sim 10^{-17} \quad \frac{\Delta m^2_{23}}{E^2} \sim 10^{-21} \]
\[
\langle \nu_i l^{(+)} b | S | a \rangle \simeq U_{li}^* \langle \nu_l l^{(+)} b | S | a \rangle_{\text{SM}}
\]

\[
\langle \nu_l l^{(+)} b | S | a \rangle_{\text{SM}} \text{ is the SM matrix element of the decay}
\]

\[
a \to b + l^{(+)} + \nu_l
\]

In the matrix element dependence on \( \nu_i \) enters through \( U_{li}^* \)

\[
|f\rangle \simeq |\nu_l\rangle |l^+\rangle |b\rangle \langle \nu_l l^+ b | S | a \rangle_{\text{SM}}
\]

\[
|\nu_l\rangle = \sum_i U_{li}^* |\nu_i\rangle
\]

"Mixed" flavor neutrino \( \nu_l \) which is produced together with \( l^+ \) is described by the coherent state \( |\nu_l\rangle \)
Evolution equation in Quantum field theory is the Schrödinger equation for states

$$\frac{d}{dt} |\Psi(t)\rangle = H |\Psi(t)\rangle$$

If $|\Psi(0)\rangle = |\nu_l\rangle$ at the time $t$ for neutrino state in vacuum we have

$$|\Psi(t)\rangle = \sum_i |\nu_i\rangle e^{-iE_it} U_{li}^*,$$

$$E_i = \sqrt{p_i^2 + m_i^2}$$

Developing over the flavor neutrino states we find

$$|\Psi(t)\rangle = \sum_{l'} |\nu_{l'}\rangle (\sum_i U_{l'i} e^{-iE_it} U_{li}^*)$$
Neutrinos detection. Let us consider the CC process

$$\nu_{l'} + N \rightarrow l' + X$$

Neglecting extremely small $\frac{\Delta m^2}{E^2}$ terms we have

$$\langle l'X|S|\nu_iN \rangle \sim \langle l'X|S|\nu_{l'}N \rangle_{SM} \ U_{l'i}$$

From unitarity of $U$ we find

$$\langle l'X|S|\nu_{l'}N \rangle = \sum_i \langle l'X|S|\nu_iN \rangle U_{l'i}^* \sim \langle l'X|S|\nu_{l'}N \rangle_{SM}$$

The normalized $\nu_l \rightarrow \nu_{l'}$ transition probability is given by

$$P(\nu_l \rightarrow \nu_{l'}) = \left| \sum_i U_{l'i} e^{-i(E_i - E_k)t} U_{li}^* \right|^2$$
Neglecting in matrix elements $\frac{\Delta m_{ik}^2}{E^2}$ we come to the following conclusion

- States of flavor neutrinos $\nu_e$, $\nu_\mu$ and $\nu_\tau$ and neutrino transition probability do not depend on neutrino production and detection processes

- Matrix elements of neutrino production and detection processes are given by the Standard Model

Neutrino oscillations are taking place if neutrino state $|\Psi(t)\rangle$ is a superposition of states of neutrinos with different masses and different energies (non stationary neutrino state)

The non stationary nature of neutrino oscillations was advocated by B. Pontecorvo and his collaborators in early neutrino oscillation papers
In the accelerator K2K and MINOS experiments time of neutrino production and neutrino detection was measured. In the K2K experiment $\nu_\mu$'s were produced in $1.1 \mu s$ spills. After the time $t \simeq L/c \simeq 0.8 \cdot 10^3 \mu s$ $\nu_\mu$ were detected by the S-K. It was found an agreement with the S-K atmospheric neutrino oscillation results. Thus, in this experiment non stationary picture of neutrino oscillations was confirmed.

Is this a general feature of neutrino oscillations? Are neutrino oscillations possible also in a stationary case?
Oscillation phase

\[ \phi_{ki} = (E_i - E_k) t \simeq (p_i - p_k) t + \frac{\Delta m^2_{ki}}{2E} t \]

The first term can be comparable with the second one.

\[ (p_i - p_k) \simeq a \frac{\Delta m^2_{ki}}{2E} \quad |a| \lesssim 1 \]

Experimental data are described if oscillation phase is given by

\[ \phi_{ki} \simeq \frac{\Delta m^2_{ki}}{2E} L \]

Thus, in the approach based on the Schrodinger equation, we need to assume that

\[ p_i = p_k = p \]

This was original assumption of B. Pontecorvo and his collaborators.
Wave function approach to neutrino propagation

We assume that in a weak process $\nu_i$ with momenta $p_i^\alpha$ are produced coherently. Wave function of neutrino is the superposition of plane waves. According to Dirac equation

$$E_i = \sqrt{p_i^2 + m_i^2}$$

Neutrino wave function

$$\Psi_{\nu_l}(x) = \sum_i e^{-i p_i^\alpha x_\alpha} U_{li}^* |i\rangle$$

describes propagation in space and time of a superposition of plane waves ($|i\rangle$ describes neutrino with mass $m_i$ and helicity equal to -1).

The transition probability is given by

$$P(\nu_l \rightarrow \nu_{l'}) = | \sum_i U_{l'i} e^{-i (p_i^\alpha - p_k^\alpha) x_\alpha} U_{li}^* |^2$$

Transitions are due to the fact that different waves after time $t$ and distance $\vec{x}$ gain different phases.
Oscillation phase

\[ \phi_{ik} = (E_i - E_k)t - (p_i - p_k)x \]

General case \( E_i \neq E_k, \ p_i \neq p_k \)

\[ \phi_{ik} \simeq \frac{\Delta m_{ik}^2}{2E} t - (p_i - p_k)(x - t) \]

Independently on the values of the momenta, the second term is equal to zero \( (x = t) \). For the oscillation phase we obtain the standard expression

\[ \phi_{ik} \simeq \frac{\Delta m_{ik}^2}{2E} t \]

Stationary case \( E_i = E_k \) Oscillation phase

\[ \phi_{ik} = -(p_i - p_k)x = \frac{\Delta m_{ik}^2}{2E} x \]

If propagating neutrinos are described by a coherent superposition of plane waves oscillations are possible also in the stationary case. Oscillation phase is given by the standard expression
Time-energy uncertainty relation for neutrino oscillations

Uncertainty relations are based on the Cauchy-Schwarz inequality

\[ \Delta A \Delta B \geq \frac{1}{2} |\langle \psi | [A, B] |\psi\rangle| \]

Where \( A \) and \( B \) are two Hermitian operators and \( |\psi\rangle \) is any state.

The Heisenberg uncertainty relations are a direct consequence of the commutation relations for \( A \) and \( B \).

For example

\[ [p, q] = \frac{1}{i} \rightarrow \Delta p \Delta q \geq \frac{1}{2} \]

Has universal form (does not depend on the state \( |\psi\rangle \)).

The time-energy uncertainty relation has a different character. Time in quantum theory is a parameter; there is no operator which corresponds to time.

Mandelstam and Tamm method is based on the fact that the evolution of a quantum system is determined by the Hamiltonian.
For any operator $O_H(t)$ in the Heisenberg representation

$$i \frac{d}{dt} O_H(t) = [O_H(t), H]$$

From this relation and the Cauchy-Schwarz inequality we have

$$\Delta E \Delta O_H(t) \geq \frac{1}{2} |\frac{d}{dt} O_H(t)|$$

Nontrivial constraints only for non stationary processes

We choose

$$O = |\nu_i\rangle \langle \nu_i|$$

Assuming that $|\Psi(0)\rangle = |\nu_i\rangle$ we find

$$\overline{O}(t) = P_{\nu_i \rightarrow \nu_i}(t)$$

where $P_{\nu_i \rightarrow \nu_i}(t)$ is the survival probability
The M-T inequality takes the form
\[ \Delta E \geq \frac{1}{2} \frac{|\frac{d}{dt} P_{\nu_l \rightarrow \nu_l}(t)|}{\sqrt{P_{\nu_l \rightarrow \nu_l}(t) - P_{\nu_l \rightarrow \nu_l}^2(t)}} \]

If we integrate over the time interval \(0 \leq t \leq t_{1\text{min}}\) (\(t_{1\text{min}}\) is the time at which the survival probability reaches the first minimum), the time-energy uncertainty relation takes the form
\[ \Delta E \Delta t \geq \frac{1}{2} \left( \frac{\pi}{2} - \arcsin(2 P_{\nu_l \rightarrow \nu_l}(t_{1\text{min}}) - 1) \right), \quad \Delta t = t_{1\text{min}} \]

For \(\nu_\mu \rightarrow \nu_\mu\) transitions driven by \(\Delta m_{23}^2\) we have
\[ \Delta t = t_{1\text{min}} = 2\pi \frac{E}{\Delta m_{23}^2} \]

Taking into account that \(\sin^2 2\theta_{23} \simeq 1\) we obtain the time-energy uncertainty relation
\[ \Delta E \Delta t \gtrsim \frac{\pi}{2} \]

It is satisfied in atmospheric S-K and accelerator K2K and MINOS experiments.
For $\bar{\nu}_e \rightarrow \bar{\nu}_e$ transition driven by $\Delta m_{12}^2$ we have
\[ \Delta E \Delta t \gtrsim 2 \sin 2\theta_{13} \]

Because $\sin^2 2\theta_{13} \lesssim 2 \cdot 10^{-1}$ T-E uncertainty relation gives much weaker constraint on $\Delta E$ in this case

Is time-energy uncertainty relation an universal feature of neutrino oscillations?
Mössbauer neutrino experiment

It was proposed by Raghavan an experiment on the detection of the tritium $\bar{\nu}_e$ with energy $\simeq 18.6$ keV in the recoilless transitions

$$3^\text{H} \rightarrow 3^\text{He} + \bar{\nu}_e, \quad \bar{\nu}_e + 3^\text{He} \rightarrow 3^\text{H}$$

Oscillation length in such experiment $L_{\text{osc}}^{(23)} \simeq 18.6 \text{ m}$

It was estimated by Raghavan that $\Delta E \simeq 8.4 \cdot 10^{-12}$ eV and $\sigma_R \simeq 3 \cdot 10^{-33} \text{ cm}^2$

(For much more pessimistic estimates see W. Potzel ArXiv: 0810.2170)

$\Delta E$ which drives neutrino transition during the time $t_{1\text{min}}^{(23)}$ must satisfy the inequality

$$\Delta E \geq \frac{1}{2\pi} \sin 2\theta_{13} \frac{\Delta m_{23}^2}{E}$$

If $\sin 2\theta_{13} \neq 0$ a constraint on $\Delta E$
\[
\sin^2 2\theta_{13} = 2 \cdot 10^{-1} \quad \text{(CHOOZ bound)}
\]
\[
\Delta E \geq 9 \cdot 10^{-9} \text{ eV}
\]
\[
\sin^2 2\theta_{13} = 10^{-2} \quad \text{(T2K, Daya Bay, ...)}
\]
\[
\Delta E \geq 2 \cdot 10^{-9} \text{ eV}
\]

Estimated energy uncertainty for Mössbauer neutrinos
\[
\Delta E \simeq 8.4 \cdot 10^{-12} \text{ eV}
\]
does not saturate time-energy uncertainty relation.

If neutrino oscillations will be observed in Mössbauer neutrino experiment in this case the time-energy uncertainty relation is not a characteristic feature of the phenomenon of neutrino oscillations.

This is equivalent to the statement that in the case of the observation of neutrino oscillations in the Mössbauer neutrino experiment non stationarity is not an universal feature of neutrino oscillations.
